(Rceived 15 September 2014; revised manuscript received 21 November 2014; published 22 December 2014)

Background: Uncertainties in adopted models of particle + nucleus optical-model potentials directly influence the accuracy in the theoretical predictions of reaction rates as they are needed for reaction-network calculations in, for instance, $\gamma$-process nucleosynthesis. The improvement of the $\alpha$ + nucleus optical-model potential is hampered by the lack of experimental data at astrophysically relevant energies especially for heavier nuclei.

Purpose: Measuring the $^{187}\text{Re}(\alpha, n)^{190}\text{Ir}$ reaction cross section at sub-Coulomb energies extends the scarce experimental data available in this mass region and helps understanding the energy dependence of the imaginary part of the $\alpha$ + nucleus optical-model potential at low energies.

Method: Applying the activation method, after the irradiation of natural rhenium targets with $\alpha$-particle energies of 12.4 to 14.1 MeV, the reaction yield and thus the reaction cross section were determined via $\gamma$-ray spectroscopy by using the Cologne Clover Counting Setup and the method of $\gamma \gamma$ coincidences.

Results: Cross-section values at five energies close to the astrophysically relevant energy region were measured. Statistical model calculations revealed discrepancies between the experimental values and predictions based on widely used $\alpha$+nucleus optical-model potentials. However, an excellent reproduction of the measured cross-section values could be achieved from calculations based on the so-called Sauerwein–Rauscher $\alpha$ + nucleus optical-model potential.

Conclusion: The results obtained indicate that the energy dependence of the imaginary part of the $\alpha$ + nucleus optical-model potential can be described by an exponential decrease. Successful re-productions of measured cross sections at low energies for $\alpha$-induced reactions in the mass range $141 \leq A \leq 187$ confirm the global character of the Sauerwein–Rauscher potential.

1. INTRODUCTION

The $\gamma$ process [1,2] is an important part of the nucleosynthesis of the $p$ nuclei, i.e., those 30 to 35 neutron-deficient heavy isotopes whose solar-system abundance cannot be explained by neutron-capture processes [3–6]. According to this concept, isotopes whose solar-system abundance cannot be explained by neutron-capture processes [3–6]. According to this concept, isotopes whose solar-system abundance cannot be explained by neutron-capture processes [3–6]. According to this concept, isotopes whose solar-system abundance cannot be explained by neutron-capture processes [3–6].

For the prediction of branching points and for reliable calculations of isotopic abundances stemming from the $\gamma$-process reaction network, reaction rates of the participating reactions have to be known precisely. The enormous number of reactions as well as the fact that many reactions are not easily accessible via experimental measurements create needs for theoretical predictions of reaction cross sections. For this purpose, the Hauser–Feshbach statistical model is widely used [10,11]. The uncertainties in its predictions can be traced back to uncertainties in nuclear physics input parameters such as $\gamma$-strength functions, nuclear level densities, and particle + nucleus optical-model potentials [5,12].

The absence of reliable experimental data, in particular for very heavy nuclei, hampers the drawing of final conclusions about the quality of, for instance, adopted models of $\alpha$ + nucleus optical-model potentials (OMPs). For very heavy nuclei with masses $A > 140$, the $(\gamma, \alpha)$ branching becomes more and more important and, therefore, also the influence of the adopted models for $\alpha$ OMPs. Usually, the parameters of an optical-model potential are fit to scattering data far above the Coulomb barrier [5]. But extrapolations of parametrizations of $\alpha$ OMPs to the astrophysically relevant energy region often fail to reproduce cross-section measurements for $\alpha$-capture reactions (see, e.g., Refs. [13–20] and references therein).

This is mainly due to the energy dependence of the imaginary part of the $\alpha$ OMP. It was found that, at center-of-mass energies below the Coulomb barrier, the depth of the $\alpha$ OMP should be strongly decreased [21].

Since $\alpha$ scattering becomes indistinguishable from Rutherford scattering at sub-Coulomb energies, investigations of the character of the $\alpha$ OMP can be better achieved by the study of $\alpha$-induced reaction cross sections, as is done in this work. Concerning $\gamma$-process nucleosynthesis, the investigation of...
(α,γ) reactions would be the preferable choice. At energies achievable in experiments (α,γ), reaction cross sections are usually quite sensitive to the γ width which is composed of γ-strength function and nuclear level densities which are uncertain as well [5,6,12]. Therefore, uncertainties in theoretical predictions are not only influenced by the adopted α strengths but also by the uncertainties in the input of the γ width.

For (α,n) reactions, this is often not the case. Figure 1 shows the sensitivity of the 187Re(α,n)190Ir reaction to the variation of the α (red line), γ (black dotted line), and neutron widths (blue dashed line) as a function of center-of-mass energy [22]. The cross section is insensitive to the proton width. See text for details.

![Diagram of cross-section sensitivity](image)

FIG. 1. (Color online) Sensitivity of the laboratory cross section for the 187Re(α,n)190Ir reaction to the variation of the α (red line), γ (black dotted line), and neutron widths (blue dashed line) as a function of center-of-mass energy [22]. The cross section is insensitive to the proton width. See text for details.

resulting cross-section values and comparisons to statistical model calculations will be presented in Secs. V and VI.

II. THE ACTIVATION TECHNIQUE

During the irradiation the number of produced 190Ir nuclei \( N_{Ir} \) is given by

\[
N_{Ir} = \Phi(t) N_{Re} - \lambda N_{Ir},
\]

where \( \Phi(t) \) denotes the flux of α particles, \( \sigma \) is the cross section, \( N_{Re} \) is the number of 187Re nuclei within the target material, and \( \lambda \) is the decay constant of 190Ir. For a constant flux of projectiles [\( \Phi(t) = \Phi \)] and a vanishing number of 190Ir nuclei at the beginning of the activation [\( N_{Ir}(t_0) = 0 \)] the solution to this differential equation is given by

\[
N_{Ir}(t) = \frac{\sigma \Phi N_{Re}}{\lambda} (1 - e^{-\lambda t}).
\]

Generally, the flux of projectiles is not constant over the whole irradiation period due to several technical limitations, e.g., extraction of ions out of the ion source, transmission through the accelerator, etc. However, this problem can be solved by measuring the accumulated charge on the target during the activation in short time intervals. Assuming that the flux of projectiles is constant within these short time intervals, Eq. (3) can be solved iteratively for the whole irradiation time:

\[
N_{Ir}^{i+1} = N_{Ir}^{i} e^{-\lambda \Delta t_{i+1}} + \frac{\sigma \Phi N_{Re}^{i+1}}{\lambda} (1 - e^{-\lambda \Delta t_{i+1}}).
\]

After the irradiation, the number of 190Ir nuclei can be determined by the spectroscopy of their decay. In the present case, this was done by observing the consecutive γ decay of levels populated in 190Os by using the Cologne Clover Counting Setup (see Sec. IV). By taking into account the number of events in the full-energy peak \( N_{\gamma} \), the absolute full-energy peak efficiency \( \epsilon_{\gamma} \), and the relative live time \( \tau \) of the experimental setup as well as the absolute intensities of the specific γ-ray transition \( I_{\gamma} \), the cross section of the reaction can be calculated via

\[
\sigma = \frac{\lambda N_{\gamma} e^{\lambda t_{W}}}{N_{Re} \epsilon_{\gamma} (1 - e^{-\lambda t_{W}}) f_{ac}}.
\]

Here, \( t_{W} \) denotes the time between the end of the irradiation and the beginning of the counting and \( t_{C} \) the time of measurement with the Cologne Clover Counting Setup, respectively. The factor \( f_{ac} \) corrects for decaying nuclei during the irradiation and the nonconstant particle-flux:

\[
f_{ac} = \frac{\sum_{I \in \Phi} (1 - e^{-\lambda t_{i}}) e^{-\lambda (t_{A} - t_{i})}}{\sum_{I \in \Phi} (1 - e^{-\lambda t_{i}}) e^{-\lambda (t_{A} - t_{i})}}.
\]

In this formula, \( \Phi \) denotes the α-particle flux in a time interval \( \Delta t_{i} \), \( t_{i} \) is the sum of the first \( i \) time intervals, and \( t_{A} \) is the end of the activation.

III. TARGET PREPARATION AND ACTIVATION

Rhenium targets with natural isotopic abundance were used, consisting of 62.6% 187Re and 37.4% 185Re. Aluminum was used as backing material. To avoid chemical reactions of
rhenum with aluminum, an additional layer of tantalum was placed between the target and the backing material.

The thicknesses of the targets were determined by Rutherford backscattering spectrometry (RBS) at the RUBION Dynamitron Tandem accelerator in Bochum, Germany. This method is based on the elastic scattering of ions, in this case He$^+$ ions, in the target material under backward angles. The thickness of the target can then be calculated from the energy loss of the ions inside the target material. The initial energy of the He$^+$ ions was 2 MeV ± 1 keV. For the detection of the ions, a silicon detector was placed at a distance of 35 mm from the center of the target, resulting in a solid angle coverage of 1.91 ± 0.07 msr. For all five targets, the measured thicknesses were between 135 and 212 μg/cm$^2$. To ensure no material loss during the activation and the transportation, an additional RBS measurement was performed afterwards. It was shown that, within the uncertainties, no material vanished.

The targets were activated at five different α-particle energies between 12.4 and 14.1 MeV at the cyclotron of PTB in Braunschweig, Germany [24]. The activation durations were between 3 and 24 h at α-beam currents between 1.0 and 2.1 μA. The energy of the α particles was determined by two analyzing magnets and a time-of-flight measurement with an uncertainty of ±25 keV [25]. An additional uncertainty in the activation energy due to the thickness of the targets was considered. The effective α-particle energy $E_\alpha$ was obtained by correcting the incident energy of the α particles, $E_0$, by their energy loss $\Delta E$:

$$E_\alpha = E_0 - \frac{\Delta E}{2}. \quad (7)$$

The energy loss was obtained using TRIM (v. 2013) simulations [26]. Depending on the thicknesses of the targets and the incident α-particle energies, the energy loss was found to be between 18 and 32 keV. Additional calculations using LISE++ [27] were in excellent agreement with the TRIM simulations. During the activation, the targets were water cooled to guarantee the thermodynamic stability of the target material. A cooling trap at liquid-nitrogen temperature was installed to avoid build up of carbon on the target surface. The α particles were stopped in the aluminum backing and the target holder served as a Faraday cup. For a reliable charge collection, a negative voltage of $U_b = -300$ V was applied to the aperture of the chamber to suppress secondary electrons. The α-beam current was measured by integrating the collected charge on the target in intervals of 60 s. For the charge collection an uncertainty of 1% was taken into account. Detailed information about the targets and activation parameters is listed in Table I.

IV. γ-RAY SPECTROSCOPY AT COLOGNE CLOVER COUNTING SETUP

After the irradiation, the targets were transported to Cologne to be analyzed by using the Cologne Clover Counting Setup at the Institute for Nuclear Physics of the University of Cologne. This setup has successfully been used before to determine cross sections of α-induced reactions; see, e.g., Refs. [20,28].

The Cologne Clover Counting Setup consists of two clover-type high-purity germanium (HPGe) detectors in a close face-to-face geometry covering a solid angle of almost 4π. Due to the smaller crystals in comparison to a single-crystal HPGe detector of the same size, summing effects are less pronounced. Furthermore, the higher granularity allows the measurement of γγ coincidences between the clover leaves. As can be seen in Fig. 2, both Clover detectors are mounted on a rail system allowing a precise variation of the distance between the target and the detectors. In addition, both Clover detectors can be equipped with bismuth-germanate (BGO) shields for an active Compton-background suppression. The whole setup is shielded by 10 cm of lead and 3 mm of copper against natural radioactivity and x-ray radiation, respectively.

The preamplifier signals of each Clover leaf are processed digitally by using DGF-4C Rev. F modules from the company XIA [29,30]. The digitization is performed with a depth of 14 bits and a frequency of 80 MHz. After the extraction of energy and time information, the data are stored in an event-by-event listmode format. This allows the offline analysis of γγ coincidences which is important in order to further reduce the background in the measured spectra and, therefore, to determine the total reaction cross section in a range of a few μb (see Sec. V B).

The efficiency calibration for the setup was performed using $^{152}$Eu, $^{57}$Co, and $^{137}$Cs calibration sources. For a reliable full-energy peak efficiency, corrections considering
summing effects have been taken into account. For this, two measurements were performed. One at a target-detector distance of 10 cm where summing effects are negligible and one at a distance of 1.3 cm. The photopeak efficiencies of $\gamma$-ray transitions of $^{57}$Co and $^{137}$Cs which are not affected by coincidence summing were used to calculate a scaling factor which accounts for the difference in geometrical efficiency between the far- and the close-distance measurements. The measured values of $^{152}$Eu were fit by using a sum of exponential functions. This fit function was then rescaled by using the geometrical scaling factor to obtain a function which represents the photopeak efficiency of the Cologne Clover Counting Setup in the close-distance geometry.

Additionally, the Cologne Clover Counting Setup was implemented in a GEANT4-based Monte Carlo simulation [31,32]. Hence, it was possible to obtain a simulated full-energy peak efficiency in the energy region between 20 and 1500 keV. In Fig. 3 the measured full-energy peak efficiencies as well as the simulated efficiency curve are presented as a function of the $\gamma$-ray energy.

Due to the granularity of the Clover detectors, the geometrical efficiency is reduced in comparison to a one-crystal HPGe detector of the same composite size, resulting in a smaller efficiency for a complete energy deposition. An incomplete energy deposition of $\gamma$ rays leads to an increased Compton background and a decreased full-energy peak efficiency [33]. However, Compton-scattered $\gamma$ rays could enter and deposit their remaining energy in the active volume of another Clover leaf. Adding back the energy of coincident events of one Clover detector could thus lead to a reproduction of the full-energy event. This so-called addback increases the efficiency of the detection system, although it leads to worse energy resolution [33].

To study the influence of an addback on the efficiency of the detection setup, an algorithm for the summing procedure was implemented in the analysis software and tested performing calibration measurements with $^{152}$Eu and $^{60}$Co. The distance between the source and the detectors during this measurement was equal to the one used for the activation measurement.

The algorithm provides three different operation modes for the Clover detectors. In singles mode, all crystals of the Clover are treated as individual detectors and the resulting spectrum represents the sum of all singles spectra. In direct mode, all events with multiplicity $m > 1$ are ignored. The addback-mode spectrum is obtained by the sum of the direct-mode spectrum and the reconstructed events by applying the addback.

The gain in efficiency by applying an addback can be expressed by a so-called addition factor [33]:

$$ g = \frac{\epsilon_{\text{add}}}{\epsilon_{\text{dir}}} . $$

This formula expresses the ratio between the number of events in the full-energy peak of the spectrum obtained by operating the Clover Setup in addback and direct modes. This addition factor $g$ was found to depend logarithmically on the $\gamma$-ray energy [33]. For the Cologne Clover Counting Setup, the gain in efficiency can be described by

$$ g(E_\gamma) = [0.19 (2)] \log E_\gamma - 0.92 (1) . $$

The photopeak efficiency of the Cologne Clover Counting Setup operated in addback mode is also illustrated in Fig. 3. Figure 4 shows a comparison of the Compton background of $\gamma$-ray spectra measured in direct, singles, and addback modes for a $^{60}$Co calibration source. The comparison shows the expected strong reduction of the Compton background by applying an addback to the measured data. The spectra were taken for the same distance between the source and the detectors as it was during the activation experiment. The average counting rate in the detectors was about 3 kcps. The relative reduction of all events in the Compton background for the addback-mode spectrum was about 33% for the measurement of the $^{60}$Co calibration source in comparison to the singles-mode spectrum.

Applying the addback to the $\gamma$-ray spectroscopy data of the activated $^{187}$Re targets does not lead to satisfactory results. Due to the $\gamma$-ray-transition cascades in $^{190}$Os and the increased geometrical efficiency by operating the Clovers in addback...
MEASUREMENT OF THE $^{187}\text{Re}(\alpha,n)$ ...  

![Graph](https://example.com/graph.png)

mode, summing effects are more pronounced, leading to a reduction in photopeak efficiency. In Fig. 5 the $\gamma$-ray spectra of $^{190}\text{Os}$ are shown with and without the application of the addback. The measured background spectrum was rescaled and also drawn for comparison. In contrast to the measurement of the $^{60}\text{Co}$ calibration source (see Fig. 4), by applying an addback to the data of the activation experiment, the reduction of the Compton background is strongly decreased. This indicates already that the main source of the measured background stems from Compton-scattered events from the crystals of the Clovers and partly in environmental material. Since such events cannot be reconstructed by applying an addback, the Compton-background reduction is smaller than needed to balance the more pronounced summing effects, especially in the relevant energy region between 360 and 615 keV (see Fig. 5). Thus, the use of an addback leads to peak-to-background ratios which are smaller than those in the summed singles spectra and was therefore not used for the further analysis.

**V. DATA ANALYSIS**

**A. $\gamma$ decays of $^{190}\text{Os}$ levels**

Figure 6 shows a simplified level scheme of the $^{190}\text{Os}$ nucleus where only the strongest $\gamma$-ray transitions are shown. For an activation energy of $E_{\alpha} = 13.7$ MeV, seven $\gamma$-ray transitions of $^{190}\text{Os}$ could be identified. Unfortunately, the strongest $\gamma$-ray transition with a $\gamma$-ray energy of 186.6 keV could not be used for the determination of the total cross section due to contributions stemming from contaminants in the target material activated in the beam.

Although using clover-type HPGe detectors should reduce summing effects, the summing out of events is still not negligible.

For this, the GEANT4-based Monte Carlo simulation was used in order to study the summing effects due to the observed $\gamma$-ray cascades; see Fig. 6. The full-energy peak efficiency of all $\gamma$-ray transitions was simulated twice. First, as a single $\gamma$-ray transition and afterwards within its specific $\gamma$-ray cascade. The ratio of the full-energy peak efficiencies yields the correction factor for summing out. Hence, it is possible to correct the obtained events in the full-energy peak for summing effects. The contribution of summed-out events was found to vary between 6.9% and 22.2% depending on the specific $\gamma$-ray transition. Table II lists the strongest $\gamma$-ray transitions in $^{190}\text{Os}$, their absolute $\gamma$-ray intensities $I_{\gamma}$, their photopeak efficiencies $\epsilon_{\gamma}$, and their summing correction factor $\xi$.

In the $\gamma$-ray spectra with the highest intensities of $^{190}\text{Os}$, the peak-to-background ratios were found to be between 0.5% and 4%. Therefore, for the analysis of the $\gamma$-ray spectra of the

other targets, a strong background reduction had to be applied for a reliable determination of the events in the full-energy peaks.

B. $\gamma\gamma$-coincidence method

Since the activity of the activated targets was low, the $\gamma$-ray intensities in the measured $\gamma$-ray spectra were not sufficient for all $\alpha$-particle energies. Therefore, the $\gamma\gamma$-coincidence method was used for further reducing the background in the measured $\gamma$-ray spectra. This method is based on the selective observation of detected $\gamma$-ray events which are in coincidence with another event with an energy in a specific range. In Fig. 7, the power of the $\gamma\gamma$-coincidence method is illustrated for the case of the $^{187}\text{Re}(\alpha, n)^{190}\text{Ir}$ reaction at an energy of $E_\alpha = 13.7$ MeV. Figure 7(a) shows the summed singles spectra of both Clover detectors for an energy region between 360 and 615 keV. Five of the most intense $\gamma$-ray transitions in $^{190}\text{Os}$ are in coincidence with the 186.6 keV ground-state transition; see Fig. 6. By taking into account only those events observed in coincidence with this ground-state transition, the peak-to-background ratio can be improved by a factor of two to ten depending on the specific $\gamma$-ray transition. See text for details.

peak in the coincidence spectrum obtained by gating on events with an energy of $E_\gamma^{\text{cut}}$ is

$$N_\gamma(E_\gamma^{\text{cut}},E_\gamma) \propto D(t_1,t_2) \epsilon_\gamma I_\gamma \epsilon_\gamma^{\text{cut}} I_\gamma^{\text{cut}}.$$  

The full-energy peak efficiency in the coincidence spectra can then be obtained by the product of the constant

$$\eta = \frac{N_\gamma(E_\gamma)}{N_\gamma(E_\gamma^{\text{cut}},E_\gamma^{\text{cut}})},$$

and the number of events in the full-energy peak in the coincidence spectrum. These parameters are independent of the activity of the targets and depend only on the efficiencies and the absolute intensities of the observed $\gamma$-ray transitions. Consequently, these measured $\eta$ parameters can be used for the determination of the cross-section values for all the other activation energies. This method was already successfully applied during the measurement of the $^{141}\text{Pr}(\alpha,n)^{144}\text{Pm}$ cross section [20].

C. Determining total-cross-section values

The total-cross-section values for the $^{187}\text{Re}(\alpha,n)^{190}\text{Ir}$ reaction were calculated according to Eq. (5) in Sec. II. For an $\alpha$-particle energy of 13.7 MeV, cross-section values were obtained from full-energy peak events of six $\gamma$-ray transitions. The values for the other activation energies were obtained by applying the $\gamma\gamma$-coincidence method as described in Sec. V B.

The $\eta$ parameters were first calculated for an $\alpha$-particle energy of 13.7 MeV. Only three of six parameters, e.g., for the 371, the 407, and the 605 keV $\gamma$-ray transition, could also be calculated from the $\gamma$-ray spectrum for an activation energy of 14.1 MeV. For the further analysis, the weighted mean of the $\eta$ parameters of these three $\gamma$-ray transitions were used to calculate the total number of full-energy peak events for the targets activated with lower $\alpha$-particle energies.

Summing-correction factors calculated using the GEANT4-based simulation were used to correct the total numbers of events in order to take summing effects into account. The final values for the total cross section were obtained by calculating the weighted mean of the cross sections obtained from each $\gamma$-ray transition. For the weights, we used the statistical uncertainties for the efficiency ($<10\%$), the $\gamma$-ray intensities ($<5\%$), the $\eta$ parameters ($<20\%$), the summing correction ($<8\%$), and the number of events in the area of the full-energy peak ($<30\%$).

VI. RESULTS

The $^{187}\text{Re}(\alpha,n)$ reaction cross sections for $\alpha$-particle energies between 12.4 and 14.1 MeV range from 0.85 to 30.4 $\mu$b. The uncertainties given for the cross-section values for each $\gamma$-ray transition as well as for the weighted means include systematical uncertainties of the photopeak efficiency as well as the uncertainties for the number of $\alpha$ particles, the number of target nuclei, and the half-life ($\approx 10\%$). The results are given in Table III and Fig. 8. The rather large uncertainties for the final values can be traced back partly to the determination of the $\eta$ parameters and the low intensity in the $\gamma$-ray spectra and partly to the large summing correction.
TABLE III. Results of the activation experiment. For each α-particle energy, the measured cross-section values for the different γ-ray transitions are shown. The last column shows the weighted average of the obtained cross sections.

As mentioned earlier, the $^{187}$Re($α,n$) cross section is almost only sensitive to the $α$ width in the measured energy range. Thus, deviations of theoretical predictions obtained by statistical-model calculations from the measured values are mainly caused by the accuracy of the adopted model for the $α$ OMP.

Therefore, calculations using the statistical-model code TALYS (v1.4) [34] were performed for different $α$ OMPs. By default, TALYS provides different implementations for $α$ OMPs. The standard $α$ OMP of TALYS is a potential derived from Watanabe [35]. The results of statistical-model calculations using this $α$ OMP fail to describe the measured data properly, as can be seen in Fig. 8. The drastic overestimation of the cross-section values results in an $χ^2$ of 285.

Other available $α$ OMPs of TALYS are different versions of the $α$ OMP described in Ref. [36] which is a global semimicroscopic approach for an $α$ OMP (in Fig. 8 named OMP1). The results of TALYS using these $α$ OMPs are much better compared to the ones using the $α$ OMPs of Watanabe with $χ^2$ between 2.7 and 5.6. Nevertheless, the predicted values are too low to reproduce the experimental values.

The $α$ OMP of McFadden and Satchler [37] was derived from extensive elastic $α$-scattering data at comparably high energies. Therefore, it predicts elastic scattering and reaction data at high energies quite well but often seems to fail to reproduce experimental values at low energies [20] mainly due to the energy-independent imaginary part of the potential (see below). This is also the case for the $^{187}$Re($α,n$) reaction as one can see in Fig. 8 ($χ^2 = 143$). The cross-section values derived from statistical-model calculations using the $α$ OMP by McFadden and Satchler overpredict the experimental values by a factor of four. It was recently proposed by Rauscher that the deviations of the $α$ OMP of McFadden and Satchler at sub-Coulomb energies could be explained by the neglect of another inelastic channel [38]. A renormalization of the compound-formation cross section using the Coulomb excitation cross section led to a significant modification towards a smaller cross section for $^{144}$Sm($α,γ$)$^{148}$Gd [39], $^{141}$Pr($α,n$)$^{144}$Pm [20], and $^{169}$Tm($α,n$)$^{172}$Lu [40]. Following the argumentation of Ref. [38], the Coulomb excitation cross section should not be negligible in comparison to the compound-formation cross section in this case and should be subject to further investigations to confirm this claim.

Somorjai et al. have already pointed out another approach to modify the $α$ OMP to improve the reproduction of the experimentally obtained $^{144}$Sm($α,γ$)$^{148}$Gd reaction cross section [39]. They argued that the depth of the imaginary part of the potential has to decrease with decreasing energy. This was achieved by parametrizing the depth of the imaginary part by an energy-dependent Fermi-type function. Sauerwein et al. picked up the idea to improve the reproduction of $^{141}$Pr($α,n$)$^{144}$Pm cross-section values by statistical-model calculations [20]. One important requirement for their $α$ OMP was to reduce the number of parameters. The so-called Sauerwein–Rauscher potential was thus based on the parametrization of Ref. [37] and only the depth of the imaginary part was modified by a Fermi-type function:

$$ W = \frac{W_0}{1 + \exp \left( \frac{0.9E_{c.m} - E_C}{a} \right)}. $$

Hence, the depth of the imaginary part depends on the height of the Coulomb barrier $E_C$, the center-of-mass energy $E_{c.m.}$, and only one parameter $a$ for the steepness of the energy
dependence. In Ref. [20] as well as in Ref. [39], the steepness parameter was chosen to be $\alpha = 2$ MeV in order to give the best reproduction. Later, as the Sauерwein–Rauscher potential was tested on experimental data of $\alpha$-capture reaction cross-section values on $^{169}$Tm, the best reproduction was given for steepness values of $\alpha = 4$ to 6 MeV [40]. Although the $\alpha$ OMP of Ref. [37] gave the best description of the measured cross section of the $\alpha$-capture reactions on $^{167}$Yb, the results of the Sauерwein–Rauscher potential for $\alpha = 4$ to 6 MeV were very promising [28]. Motivated by its success, statistical-model calculations using the Sauерwein–Rauscher potential were also performed for the $^{187}$Re($\alpha$,n) reaction. Varying the steepness values between $\alpha = 4$ to 6 MeV resulted in an excellent reproduction of the experimental values. In Fig. 8, the theoretical predictions based on the Sauерwein–Rauscher potential are shown for a steepness value of $\alpha = 4$ MeV ($\chi^2 = 0.3$). All the other parameters were kept the same as in Ref. [20].

VII. SUMMARY AND CONCLUSION

In this work, cross-section values for the $^{187}$Re($\alpha$,n) reaction were measured at five different energies close to the astrophysically relevant energy region. The cross-section values for the lowest $\alpha$-particle energies have been extracted by means of $\gamma\gamma$-coincidence data. Statistical-model calculations performed using the TALYS code (v1.4) revealed that the theoretical prediction of cross sections at sub-Coulomb energies is still problematic. Calculations based on the default implemented $\alpha$ OMPs of Refs. [35–37] show differences of the order of one magnitude. Due to the exclusive sensitivity of the reaction cross section on the $\alpha$ transmission, these variations can be traced back to the input for the $\alpha$ OMP. The success of the Sauерwein–Rauscher potential for this measurement as well as for previous ones [20,28,40] is promising and should motivate further systematic studies of the global character of this $\alpha$ OMP.
